Abstract. Recent advances in software engineering, business process management and computational intelligence resulted in methods and techniques for developing advanced e-commerce applications as well as supporting automating e-commerce business processes. Despite this fact, up to now, the most successful e-commerce systems are still based on humans to make the most important decisions in various activities within an e-business transaction. In this context, development of automatic negotiations is one of the more important research issues. While, depending on the type of the transaction, different negotiation procedures could be utilized, only few proposed frameworks are generic and flexible enough to handle multiple scenarios. On the other hand, agent technology is often claimed to be the best approach for automating e-commerce business processes (including price negotiations). However, it is difficult to find successful large-scale agent-based e-commerce applications to confirm this claim. Here, we present negotiating agents that change their negotiation protocol and strategy through dynamic loading of negotiation modules. These, as well as other agents of different types and playing different roles have been implemented to interact within an abstract e-commerce environment. Description of this complete e-commerce system is the goal of this paper.

Key words: multi-agent systems, e-commerce, automated negotiations

AMS Subject Classification: 68T99

1. Introduction. Already long time ago the six main stages of consumer buying behavior have been conceptualized: need identification, product brokering, merchant brokering, negotiation, payment and delivery, service and evaluation (Howard, 1969). These stages have not changed when commerce moves to the Internet and becomes e-commerce. To be able to support consumers, e-commerce research involves all aspects of complex processes, spanning areas that cover business modeling, information technology and social and legal aspects (Laudon, 2004). Currently, e-commerce systems operate following the principle "to select and to accept choices". Thus users can browse through catalogues of needed goods (tickets, films, books CD’s and so on) and utilize them to make purchasing decisions. There exist systems, which support users during the product or/and merchant brokering stages of the buying process (for instance www.shopping.com). However, the most interesting part of product buying: automated negotiations, is not properly supported within B2C environments (however, limited use of automated negotiations within B2B is known to exist for some time now, and apparently was partially responsible for some of the more spectacular crashes on the New York stock market in the late 1990th).

It is exactly in the context of agent-based automated price negotiations, where a lot of research activity can be observed. Here, negotiation is a process by which group of agents communicate with another to try and come to a mutually acceptable agreement on some matter (?). While there exist many definitions of agents (?), for the purpose of this paper we will define them as: encapsulated computer programs, situated in an environment, and capable of flexible, autonomous actions focused on meeting their design objectives (?). For such agents, e-commerce is considered to be one of the paradigmatic application areas. As described in the recent survey (Kowalczyk, 2003), multi-agent technology (involving intelligent mobile agents) should have an important economical impact, by bringing efficiency to businesses (and thus improving their profitability), as well as benefitting individual users (e.g. by assuring "price-optimality" of purchases). It is exactly in the latter context where, multi-agent systems are expected to assure price fairness and reduce the negotiation time.
While a large amount of work has been devoted to study agent-negotiations, the current state of the art and practice is still rather unsatisfactory. It is thus obvious that realization of fully automatic negotiation system will demand a lot more work. Our research indicates that most currently existing automated trading systems are not robust enough to become the foundation of the next generation of e-commerce. For example, the Kasbah Trading System (?) supports buying and selling but does not include auctions; SILKROAD (?), FENAs (?) and Inter-Market (?) exist as "frameworks" but lack an implementation (which is typical for most agent systems in general (?), (?)). Claim that there is a lot more work to be done to develop real-life agent-based support for e-commerce is further supported by the fact that it is almost impossible to point out to an existing large-scale implementation of an e-commerce agent system. While a number of possible reasons for this situation have been suggested (see, for instance, (Paprzycki, 2003), one of them has been recently dispelled. It was shown that modern agent environments (e.g. JADE) can easily scale to 1500 agents and 300000 messages (Chmiel, 2004b). Since these results have been obtained on a set of 8 antiquated Sun workstations, it is easy to extrapolate the true scalability of JADE on modern computers and thus it is possible to build and experiment with large-scale agent systems. Secondly, recently new methods and techniques of software engineering, business process management and computational intelligence in support of the development of advanced e-commerce applications have been proposed. For example, we now have generic software frameworks for automated negotiation (Bartolini, 2003), Semantic Web support (ontologies and semantic Web services), at least in theory, for the full B2B e-commerce lifecycle (?), and finally, multi-agent solutions for business process management (?).

Therefore, we have set up a goal of developing, implementing and experiment with a large-scale agent-based e-commerce system. Since this is a long-term undertaking, at this stage our focus is on creating a system with a multitude of agents that play variety of roles and interact with each-other (system skeleton). Currently, we follow and combine our earlier work in two areas. This paper is a follow up to (?), (?) where we proposed a system in which agents can operate according to different business models including auctions, reverse auctions, trading, e-sales etc. This was to be made possible by constructing agents out of independently pluggable, loaded remotely on-demand modules (Paprzycki, 2004). Second, we have implemented a simplistic skeleton for an e-commerce simulation (Chmiel, 2004a) and proceeded to create a unified e-commerce environment witch supports
automatic negotiations in the case of one-to-many negotiation process and experimented with the system running on two networked computers (?). This paper is a summary of our work starting from (?, ?) and ending with (Paprzycki, 2004, ?, ?) In the paper we, first, discuss the most important issues involved in negotiations. In Section 3 we introduce the top level description of our system and agents that populate it. Here, functionalities of most important agents are illustrated through UML diagrams. We follow (in Section 4) with a summary of implementation-specific information as well as an example illustrating system’s work. We conclude with the research agenda of our team.

2. Negotiations. Let us start from conceptualizing negotiations both in theory and in the context of development of negotiating agents. Negotiation is a method for coordination and conflict resolution. Conflict can be in the form of resolving goal disparities in planning, resolving constraints in resource allocation, and resolving task inconsistencies in determining organizational structure. As indicated above, in the context of the Internet it will be autonomous agents that will be involved in negotiations. Overall, research on agent-mediated negotiation can be divided into approaches based on game theory or artificial intelligence.

Game-theoretic approach is directed towards developing optimization algorithms (e.g. Rosenschein and Zlotkin (?), AuctionBot (?). This approach takes into account both cooperative and non-cooperative agents. In the case of cooperative agents, the problem space can be divided efficiently between all agents. In (?), agents form a team, each having its own local goals and a team goal. When a conflict arises, the team members can negotiate about the matter, and give evidence supporting their stance. However, the team members are assumed to have total knowledge about the system. In non-cooperative approach, theories like Nash equilibrium are applied to the bargaining problem to find the optimum solution for agents. Their main drawback is that, due to their roots being highly theoretical, they provide us with highly abstract models that assume unrealistic properties of the game: e.g. agents are assumed to have the entire common knowledge and unbounded rationality; in addition, they are assumed to have unlimited computation power and indefinite negotiation time. This makes such approaches impossible to implement. Nevertheless, the extensive research carried out in this field helped develop other theories. An example of game-theoretic approach is the work on modeling and
implementing techniques for agents participating in auctions e.g. Dutch auction, English auction, Vickery auction, etc.

Artificial Intelligence based approaches utilizes trading heuristics for different market mechanisms (e.g. Chavez et al. (?), Faratin et al. (?)). AI techniques focus on the negotiation process rather than the outcome of the negotiation. Mostly learning approaches like decision trees, Q-learning and evolutionary algorithms have been used to improve bargaining strategies. The agents used are adaptable, realistic and sociable. AI theories are based on realistic assumptions of an imperfect world with bounded rationality and limited knowledge of the world. Since agents do not know a’priori what type of agents they are interacting with, this creates conflicts between agents. Simulations of agents learning different bargaining strategies, through genetic algorithms, have been carried out and their results have been quite promising.

When considering the practical aspects of designing multi-agent negotiations, the negotiation protocol, negotiation objects and the reasoning models (?)) need to be taken into account. Let us consider each of them separately:

- **Negotiation protocol** consists of a set of rules that govern the interaction among agents. Some examples of the rules are permissible types of participants: negotiators, third parties; negotiation states: accepting bids, negotiation closed; valid actions of the participant in particular states. Typical negotiation protocols are

  A. **FIPA English Auction Interaction Protocol**: the auctioneer seeks to find the market price of a good by initially proposing a price below that of the expected market value and then gradually raising it. Each time the price is announced, the auctioneer waits to see if any buyers will signal their willingness to pay the proposed price. As soon as one buyer indicates that it will accept the price, the auctioneer issues a new call for bids with a higher price. The auction continues until no buyers are prepared to pay the proposed price, when the auction ends. Commodity is sold only if the last accepted price exceeds the auctioneer’s (privately known) reservation price.

  B. **FIPA Dutch Auction Interaction Protocol**: the auctioneer attempts to find the market price for a good by starting bidding at a price higher than the expected market value, then
progressively reducing the price until one of the buyers accepts the price. The rate of reduction of the price is up to the auctioneer and usually a reserve minimal price is involved.

- **Negotiation objects** are ranges of issues over which agreement must be reached. These depend on the environment and can be different for different environments.

- **Reasoning model** is the apparatus that participants employ to act in line with the negotiation protocol in order to achieve their negotiation objectives. Reasoning models are the thinking machines behind the process of carrying out the negotiation. Reasoning model is a mechanism by which the next counter-offer is calculated during negotiation so that the price fits into the goal of buying some good within the specified range. Some of the strategies developed so far are argumentation, persuasion and heuristics-based. It can be safely assumed that the kind of reasoning model chosen depends on both the protocol and the negotiation object [JEN1]. Moreover, the complexity of former depends on latter.

This way of conceptualizing negotiations results in agents that have to consist of the following three main modules:

- **Communication module** - responsible for communication between the agents in a common, understandable way. Since FIPA, as a main agent standardization body, is supporting a number of communication technologies (e.g. the ACL communication language) [FIPA], we will omit this part as falling outside the scope of this note. This is especially so since this module is static one (while this could be an interesting research topic in its own rights - in this note we are not concerned with dynamically loading different communication models).

- **Protocol module** - contains general rules of negotiation; when an agent initiates negotiation, on the basis of negotiator table and/or meta-negotiations it finds out which negotiation protocol can be used and dynamically loads the correct module (from the user’s local machine or any agent server, e.g. the nearest one).

- **Strategy module** - is designed to apply the proper reasoning module so that the negotiation ends in a success. The reasoning model contains policies, which are a set of goals, actions and action
rules (triggers). In order to decide which reasoning model to use, the agent uses the mapping table. This records the earlier history of the transactions, which the agents made with the previous seller. It also lists what was the success rate for the transactions. If an entry is not found, then the agent resorts to a default strategy. To keep the agent lightweight it will carry only a part of the table, containing the "sites" most often negotiated with, while the remaining part of the table will be kept on the user's machine. In case the user's machine is off-line the default strategy will be used, again (since this will involve only sites that are visited rarely, such an occurrence should not be detrimental to the overall behavior of our system). The strategy also depends on which protocol module has been chosen. In fact, the strategy is almost restricted by that decision. For example, a strategy used for argumentation cannot be used if the protocol is an auction protocol. It should be noted that it is possible define two levels of strategies: coarse and granular. The granular strategies are tit-for-tat, conceder etc, while the coarse strategies are heuristics, using knowledge base etc. Their usage will depend on the negotiation context and the details of the selection strategy will be further studied. We expect that a special (rule-based) strategy selection meta-module will be developed. This module will, again be split between the agent, that will carry the most important rules, and the user local machine that will contain the complete module. In this way the agent will be able to get involved in negotiations even if its contact with the user's machine will be impossible to establish.

The main problem in designing mobile e-commerce agents involved in negotiations is the fact that we cannot assume that agent will know a priori which negotiation protocol will be used at a given site (we assume here, that the same site, for the same product can use at different times different negotiating protocols). This being the case, “buyer agents” would have to carry with them a large load of negotiations protocols and strategies and this would impede their mobility. This is particularly the case when sophisticated negotiation strategies are to be used (for all practical purposes we have to assume that the more sophisticated strategy, the larger the strategy module that implements it). Thus we are dealing with a clear case of the “no free lunch theorem” agents can be either mobile and lightweight or “intelligent.” To address this problem we follow the proposal
introduced in (7). There each agent consists of the skeleton and three separate modules: communication, strategy and protocol. The mobile part of an agent consists of the skeleton and the communication module (though it can be assumed that, for instance, multi-lingual communication modules can be also downloadable), while the protocol and strategy modules are downloaded after agent arrives at the e-marketplace and establishes which protocol is to be used. Then, on the basis of the history of interaction with that site, the product to be purchased, the protocol used etc. an appropriate strategy module is also loaded. Observe, that the protocol module can be public - as its content has to be the same for all agents participating, for instance, in an English auction, and thus can be loaded from "any server". It is only the strategy module that is proprietary and has to be downloaded from the "home-base". The proposed design of negotiating agents is illustrated in Figure 1; further details can be found in (7, 7).

Since the aim of our work was to test-implement an agent system, and not to deal with specific negotiation strategies, we have implemented two very simple negotiation strategies. The seller increments the price by 10 in, what we named, the Heuristics Reasoning module and by 20 in, what we named, the Argumentation Reasoning module (obviously, these names only indicate negotiation strategies that could have been used here). Currently we load these two modules randomly as a proof of concept.

3. System Description. In our work we aim at implementing a multi-agent e-commerce environment to help carrying out experiments with real-world e-commerce scenarios. Note that sometimes we use the word environment rather than system to point out the exploratory nature of our
work; i.e. we are more interested in creating an artificial agent world in which e-commerce agents perform variety of functions typically involved in e-commerce, rather than developing a particular e-commerce system targeted to solve a specific business problem that uses a limited number of application-specific agents.

3.1. System Architecture. Our e-commerce model extends and builds on the e-commerce structures presented in (Galant, 2000), (Chmiel, 2004a) and (Paprzycki, 2004). Basically, our environment acts as a distributed marketplace that hosts e-shops and allows e-clients to visit them and purchase products. Clients have the option to negotiate with the shops, to bid for products and to choose the shop from which to make a purchase. Conversely, shops may be approached "instantly" by multiple clients and consequently, through auction-type mechanisms, have an option to choose the buyer. At this stage the system is under development and has a number of limitations. (1) Only two auction protocols have been implemented. (2) The two strategy modules are only to show that such modules can be downloaded upon request. (3) We have only shops are allowed to advertise their products (clients cannot advertise goods they are seeking). (4) While various strategies could be employed to decide where to buy from (e.g. the best price, the safest offer, the most trusted offer, etc.), we are using only the best negotiated price. Obviously, these are serious restriction and we plan to address them in the near future.

Shops and clients are created through a GUI interface that links users (buyers and sellers) with their Personal Agents. However, these agents are in many ways spurious for the operation of the system. More precisely, a Personal Agent is considered to be a true representative of the user that resides on her machine and represents her interests in all aspects of e-life. Thus, in the context of our system its role is to create Client / Shop agents that will be a part of the e-commerce system; and therefore the Personal Agent is omitted from further considerations. The top level conceptual architecture of the system illustrating proposed types of agents and their interactions in a particular configuration is shown in Figure 2. Let us now describe each agent appearing in that figure (as well as Personal agents) and their respective functionalities.

A Client agent (CA) is created by the Personal agent to act within the marketplace on behalf of a user that attempts at buying something. Similarly, a Shop agent represents user who plans to sell something within the e-marketplace. After being created both Shop and Client agents register
with the CIC agent to be able to operate within the marketplace. Returning agents will receive their existing IDs. In this way we provide support for the future goal of agent behavior adaptability. Here, agents in the system are able to recognize status of their counterparts and differentiate their behavior depending if this is a "returning" or a "new" agent that they interact with.

There is only one Client Information Center (CIC) agent in the system (in the future we may need to address this potential bottleneck [Chmiel 2004b]). It is responsible for storing, managing and providing information about all "participants" existing in the system. To be able to participate in the marketplace all Shop and Client agents must register with the CIC agent, which stores information in the Client Information Database (CICDB). The CICDB combines the function of client registry, by storing information about and unique IDs for all users and of yellow pages, by storing information about of all shops known in the marketplace (?). Thus Client agents (new and returning) communicate with the CIC agent to find out which stores are available in the system at any given time. In this way we are (i) following the general philosophy of agent system development, where each function is embodied in an agent and (ii) utilizing the publisher-subscriber mechanism based on distributed object oriented systems. Furthermore, this approach provides us with a simple mechanism of
correctly handling the concurrent accesses to a shared repository without having to deal with typical problems of mutual exclusion etc. Actually, all these problems are automatically handled by JADE’s agent communication service.

A Client agent is created for each customer that is using the system. Each Client agent creates an appropriate number of "slave" negotiation agents with the "buyer role" (Buyer agents hereafter). One Buyer agent is created for each store, within the marketplace, selling sought goods. Operation of the Client agent is depicted in Figure 3; further details can be also found in the next section.

On the supply side, a single Shop agent is created for each merchant in the system and it is responsible for creating a slave negotiation agent with the "seller role" (Seller agent hereafter) for each product sold by the merchant within her e-store. Operation of the Shop agent is depicted in Figure 4, while the Seller agent is conceptualized in Figure 5; further details can be also found in the next section.

Finally, Database agents are responsible for performing all database operations (updates and queries). For each database in the system we create one database agent (in the future we may need to address this possible bottleneck (Chmiel, 2004b). In this way we decouple the actual database management activities from the rest of the system (i.e. the database man-
JADE-BASED MULTI-AGENT E-COMMERCE ENVIRONMENT

The central part of the system operation is comprised by price negotiations. **Buyer agents** negotiate price with **Seller agents**. For this purpose **Buyer agents** migrate to the e-stores known by the **CIC agent** to carry sought after commodity. In case of multiple **Buyer agents** attempting at purchasing the same item, they may compete in an auction. Results of price negotiations are send by the **Shop agent** to the **Client agent** that decides where to attempt at making a purchase. Note that the system is fully asynchronous and thus an attempt at making a purchase does not have to result in a success as by the time the offer is made other **Buyer agents** may have already purchased the last available item. In this way we proceed with a n e-commerce model similar to the airline ticket reservation where until an actual purchase is made item is reserved, but may not be available at a later time.

Let us now illustrate operation of the system through a simplified usage scenario.

**3.2. Usage scenario.** A session with the system starts with the merchants and customers creating **Shop** and **Client** agents via the GUI pro-

---

**Fig. 4.** UML statechart diagram of the **Shop agent**.
vided by their Personal agents. A Client agent obtains name of the product of interest (possibly multiple products of interest) and a reserve price (see Figure 3). A Shop agent obtains a list of pairs (product, reserve price) and the negotiation protocol that is to be used for interactions with incoming Buyer agents. The reserve price of a Client agent is the maximum price it agrees to pay for the product. The reserve price of a Shop agent is the minimum price at which it is to agree to sell a specified product. Each Shop agent creates Seller agents, one Seller agent for each product sold (see Figure 4). Seller agents await incoming Buyer agents interested in buying their products and upon their arrival engage in negotiations with them (see Figure 5). Let us now describe what happens in the marketplace after a customer has made a purchase request, until a request is completed (Figures 3, 4 and 5 further illustrate the process).

(1) As specified above, a Client agent registers with the CIC agent. It obtains a new ID if it is a new Client or recovers its original ID if it is a returning Client. The information that an agent with a
given ID is active in the marketplace is stored in the CICDB database (this step involves interactions between the CIC agent and the CICDB agent).

(2) The Client agent queries the CIC agent to obtain the list of Shop agents selling the product it is expected to purchase. For each Shop agent on this list it creates a Buyer agent to negotiate conditions of purchase.

(3) Buyer agents migrate to Shop agent sites and query Shop agents about the negotiation protocol used in a given e-store and which Seller agent they should negotiate with. Then, Buyer agents dynamically load appropriate negotiation protocols (and, in the future, strategy modules (Parakh, 2003)) and subscribe to the designated Seller agent, waiting for the negotiation process to start.

(4) The Seller agent checks periodically (currently in 1 minute intervals) for the set of Buyer agents that subscribed to bid for its product. If this set is nonempty, it starts an auction. At the end of an auction a Seller agent informs the Shop agent about the winner. Shop agents are recording the auctions winners and inform the corresponding Client agents that a purchase is possible. The decision to buy and where to buy from is made by the Client agent, depending on the winning offers made by the Shop agents.

(5) The Client agent obtains results of auctions from the Shop agents, finds the best negotiated price and makes an attempt at purchasing the product by informing the corresponding Shop agent about the decision to buy. When the confirmation is received, it informs the customer about the result of its request: success of failure of purchase, the shop where the purchase was made from and the negotiated price.

4. Implementation and Experiment.

4.1. System Implementation. The current implementation of the proposed environment has been made within the JADE 3.3 agent platform (JADE, 2003). The main reason for this selection was the fact that JADE is one of the best modern agent environments. JADE is open-source, it is FIPA compliant and runs on a variety of operating systems including Windows and Linux. Furthermore, in (Chmiel, 2004b) we have observed its very good scalability.
JADE architecture, consisting of a platform within which agents "live" and containers, where agents "reside" matches well with our requirements. Negotiations between Seller and Buyer agents take place inside of JADE containers. There is one Main container that hosts the CIC agent. Users (customers and merchants) can create as many containers they need to hold their Client and Shop agents (e.g. one container for each e-store). Buyer agents created by the Client agents use JADE mobile agent technology to migrate to the Shop agent containers to engage in negotiations.

Figure 6 presents a mapping of our conceptual architecture from Figure 2 onto JADE. In particular, this diagram shows two machines running Personal, Shop, Client, Buyer and Seller agents, highlighting also JADE containers involved (Main container in the upper half of the figure, and Container-1 container in the lower half, separated by the horizontal dotted line). Here, continuous lines denote agent creation. Personal agent $P_1$ represents user u1 (shopper) and creates two Client agents: $C_{11}$ and $C_{12}$ to purchase items $p_1$ and $p_2$ respectively. Single-arrow dashed lines denote agent migration. Buyer agent $B_{111}$ migrates from the Main container to the Container-1 container. Double-arrow continuous lines denote negotiations. Seller agent $S_{11}$ negotiates with Buyer agents $B_{111}$ and $B_{211}$ for product $p_1$. The sample scenario from Figure 6 is discussed in more detail in section 3.2.

The current implementation is based on several Java classes organized into the following categories:
Agent classes. They are used for describing the agent types. In this category we have utilized: class ClientAgent that implements Client agents, class ShopAgent that implements Shop agents, class CIC that implements CIC agents, class NegoAgent that implements negotiating Buyer and Seller agents, classes CICDatabaseAgent and ShopDatabaseAgent that implement Client Information Database and Shop Database agents and class PersonalAgent that implements Personal agents. An agent is implemented in JADE by extending the provided Agent base class and overriding the default implementation of the methods that are automatically invoked by the platform during the agent lifecycle, including setup() and takedown(). In our implementation all agent classes extend the Agent base class except the PersonalAgent class that extends the GuiAgent class (provided by JADE).

Agent activity classes, also called behaviors. They are used for describing the activities performed by agents in the system. A behavior is an abstraction that represents an atomic activity performed by an agent. In our implementation we have used local classes for defining behaviors that describe the agent responses to FIPA messages, like INFORM and SUBSCRIBE. There are also two global classes for defining auction initiators and auction participants: class AuctionInitiator and class AuctionParticipant. Note that in the current implementation our agents are negotiating only using FIPA defined English and Dutch auction schemas, but the approach can be easily extended to other automated negotiation models. A behavior is implemented in JADE by extending the provided Behaviour abstract base class. The class Behaviour is the root of a class hierarchy abstracting various agent behavior types. We have found useful to use the class CyclicBehaviour as the base class for the class AuctionParticipant and the class FSMBehaviour as the base class for the class AuctionInitiator. As concerning the definition of the responses to FIPA messages, we have extended the class CyclicBehaviour.

Reasoning classes. They are used for the implementation of the various reasoning models employed by the negotiation agents; see (Paprzycki, 2004) for more details on the model of negotiation agents. Our implementation supports agents that dynamically load their negotiation protocols and reasoning modules. The implementation combines the Factory design pattern (Cooper, 2000) and dynamical loading of Java classes (Paprzycki, 2004).

Ontology classes. They are necessary for implementing the agent communication semantics using concepts and relations. The current implemen-
tation uses an extremely simple ontology that defines a single concept for describing Client and Shop preferences including prices, product names and negotiation protocols.

Other classes. Here including there is class PersonalAgentGUI for the implementation of the graphical user interface of Personal agents.

In our system, agent communication is implemented using FIPA ACL messages (FIPA, 1999). We have used the following messages: SUBSCRIBE, REQUEST, INFORM, FAILURE, CFP, PROPOSE, ACCEPT-PROPOSAL, REJECT-PROPOSAL, REFUSE.

SUBSCRIBE messages are used by the Shop and Client agents to register with the CIC agent and for the Buyer agents to register (to participate in auctions) with the Seller agent. REQUEST messages are used by Client agents to query the CIC agent about what shops are selling a specific product and for Client agents to ask the Shop agent for a final confirmation of a transaction. INFORM messages are used as responses to SUBSCRIBE or REQUEST messages. For example, after subscribing to the CIC agent, a Client agent will get an INFORM message that contains its ID, or after requesting the names of the shops that sell a specific product, a Client agent will receive a list of the Shop agent IDs in an INFORM message. Buyer agents are using FAILURE messages to inform the master Client agents about the unsuccessful result of an auction. Finally, CFP, PROPOSE, ACCEPT-PROPOSAL, REJECT-PROPOSAL and REFUSE messages are being used by negotiating agents.

4.2. Running the System. For the experiment, we set up JADE on 2 computers. On the first computer, the Main container is initialized. On the second computer, a second container Container-1 that is linked with the Main container on the first computer was started. On both computers we have set-up MySQL database. Both the CIC and the CICDB agents are created by default within the Main container, while the Shop and the ShopDB agent are instantiated in Container-1.

In this experiment we have chosen a simple scenario with 2 merchants – u3 and u4 and 2 customers - u1 and u2. Customer u1 is seeking products p1 and p2, while customer u2 is seeking products p1 and p3. We assume that both customers are seeking a common product – p1, in order to enable price competition. Figure 6 illustrates this scenario.

Customers and merchants used Personal agents to create Client and Shop agents. In this experiment merchants used Personal agents running in Container-1 container to create two Shop agents (Figure 7, upper left
panel) and customers used Personal agents running in Main container to create two Client agents (Figure 7, upper right panel).

The process of starting Shop agents involved their registration with the CIC agent. Hereafter, for each product offered, a Seller agent was created in Container-1, finally resulting in 6 Seller agents being created. Similarly, starting Client agents involves their registration with the CIC agent, followed by the "search" of Shop agents that sell sought products and creation of a Buyer agent for every Shop agent found. So, finally, 4 Buyer agents were created (4 Client agents send 2 Buyer agents each to 2 e-stores).

At this stage, Buyer agents move to 'Container-1 and register with appropriate Shop agents. As a result of message exchanges (Figure 7, bottom panel) negotiation protocol is identified and negotiation modules loaded by Buyer agents. Next, Buyer agents subscribe with Seller agents that sell sought products. Seller agents react to a timer that periodically triggers start of auctions with subscribed Buyer agents (an English auction in this experiment). Thus we have 6 auctions - 2 for selling each product $p_1$, $p_2$ and $p_3$. Note that because both customers $u_1$ and $u_2$ are requesting product $p_1$, Buyer agents $B_{111}$ and $B_{211}$, and respectively $B_{112}$ and $B_{212}$ are competing for buying $p_1$ from Seller agents $S_{11}$ and respectively $S_{21}$.

Figure 7 (bottom panel) presents message exchanges captured in the experiment with the help of a JADE provided sniffer agent. This figure shows: i) Shop and Client agents subscribing to the CIC agent; ii) Client agents asking the CIC agent where to find out a specific product; iii) Buyer agents subscribing to Seller agents for negotiation; iv) the start of a negotiation when a Seller agent issues a call-for-proposal request to a Buyer agent.

5. Conclusions. In this paper we have presented basic features of an e-commerce modeling agent system that we are in the process of developing. At this stage its capabilities are limited, but we have already considered a number of future research directions that we plan to pursue.

1) Currently price is the only factor determining purchase. Other factors, such as the speed of delivery, trust, history of involvement with a given merchant should be also taken into account. Overall, we plan to combine the framework for multi-section contract formation discussed in (Karp, 2003) with the software framework for automated negotiation presented in (Bartolini, 2003) and results on negotiation framework targeted to multiple buyers and sellers reported in (Srivastava, 2003).
(2) Currently only shops can advertise available commodities. We plan to extend this to the scenario in which also clients will be able to advertise their "needs".

(3) We will complete implementation of negotiation protocols. Currently we have implemented Dutch and English auctions. We will add the remaining, FIPA defined auction protocols as well as simpler strategies such as: fixed pricing, fixed pricing with a discount for volume purchases, special prices for returning customers etc.

(4) Currently we have been running our experiments on two computers, where all seller data is located in a single database. In the near future we will experiment with a larger number of computers and adjust them so that each store has a separate database. More generally, we plan to experiment with a large number of computers, clients, shops, commodities and negotiation protocols. The aim of these experiments is to establish scalability of the systems as well as locate its performance bottlenecks.
Our system works on the basis of an extremely simplistic ontology that has to be refined. In the process we plan to add, among others, features representing: delivery options (and prices), trust / reliability and other concepts useful in carrying out e-commerce processes.

Currently, the negotiation strategy module is only a placeholder (agents increase or reduce their offers - depending on the auction - by a fixed amount). A set of somewhat more realistic options will be introduced shortly.
